

Virtual memory (I)

Hung-Wei Tseng

What happens when creating a process

Dynamic allocated data: `malloc()`

Local variables,
arguments

Linux contains a `.bss` section
for uninitialized global variables

Previously, we talked about virtualization

Virtually, every process seems to have a processor/memory space, but only a few of them are physically executing/using the installed DRAM.

The Machine

Virtualizing the processor

- The mechanism
 - Non-preemptive/cooperative: the run process itself initiate context switches — by using system calls
 - Preemptive: the OS kernel can actively incur context switches — by using hardware (timer) interrupts
- The policy
 - Non-preemptive
 - First Come First Serve
 - ~~Shortest job first: SJF~~
 - Preemptive
 - Round robin
 - ~~Shortest Time-to-completion~~
 - Multi-level scheduling algorithm

Previously, we talked about virtualization

How about sharing DRAM?

Previously, we've talked about sharing the processor.

The Machine

Outline

- Why virtualize your memory
- Start with the basic proposal — segmentation
- Demand paging

Why Virtual Memory?

If we expose memory directly to the processor (I)

The Virtual Memory Abstraction

Virtual memory

Virtual memory

Virtual memory

- An **abstraction** of memory space available for programs/software/programmer
- Programs execute using virtual memory address
- The operating system and hardware work together to handle the mapping between virtual memory addresses and real/physical memory addresses
- Virtual memory organizes memory locations into "**pages**"

Demo revisit: Virtualization

- Some processes may use the same processor
- Each process has the same address for variable a, but different values.
- You may see the content of a compiled program using objdump

Demo: Virtualization

```
double a;

int main(int argc, char *argv[])
{
    int cpu, status, i;
    int *address_from_malloc;
    cpu_set_t my_set;           // Define your cpu_set bit mask.
    CPU_ZERO(&my_set);         // Initialize it all to 0, i.e. no CPUs selected.
    CPU_SET(4, &my_set);       // set the bit that represents core 7.
    sched_setaffinity(0, sizeof(cpu_set_t), &my_set); // Set affinity of this process to the defined mask, i.e. only 7.
    status = syscall(SYS_getcpu, &cpu, NULL, NULL);
    getcpu system call to retrieve the executing CPU ID
    if(argc < 2)
    {
        fprintf(stderr, "Usage: %s process_nickname\n", argv[0]);
        exit(1);
    }

    srand((int)time(NULL)+(int)getpid());
    a = rand();
    create a random number

    fprintf(stderr, "\nProcess %s is using CPU: %d. Value of a is %lf and address of a is %p\n", argv[1], cpu, a, &a);
    sleep(1);
    print the value of a and address of a

    fprintf(stderr, "\nProcess %s is using CPU: %d. Value of a is %lf and address of a is %p\n", argv[1], cpu, a, &a);
    sleep(3);
    print the value of a and address of a again after sleep

    return 0;
}
```

Process C is using CPU: 4. Value of a is 685161796.000000 and address of a is 0x6010b0
Process A is using CPU: 4. Value of a is 217757257.000000 and address of a is 0x6010b0
Process B is using CPU: 4. Value of a is 2057721479.000000 and address of a is 0x6010b0
Process D is using CPU: 4. Value of a is 1457934803.000000 and address of a is 0x6010b0
Process C is using CPU: 4. Value of a is 685161796.000000 and address of a is 0x6010b0
Process A is using CPU: 4. Value of a is 217757257.000000 and address of a is 0x6010b0
Process B is using CPU: 4. Value of a is 2057721479.000000 and address of a is 0x6010b0
Process D is using CPU: 4. Value of a is 1457934803.000000 and address of a is 0x6010b0

The same processor!

Different values

**Different values are
preserved**

**The same memory
address!**

Demo revisited

&a = 0x601090

Process A

**Process A's
Mapping Table**

Process B

**Process B's
Mapping Table**

```
#define _GNU_SOURCE
#include <unistd.h>
#include <stdio.h>
#include <stdlib.h>
#include <assert.h>
#include <sched.h>
#include <sys/syscall.h>
#include <time.h>
```

```
double a;
```

```
int main(int argc, char *argv[])
```

```
{
```

```
    int i, number_of_total_processes=4;
```

```
    number_of_total_processes = atoi(argv[1]);
```

```
    for(i = 0; i < number_of_total_processes-1 && fork(); i++);
```

```
    srand((int)time(NULL)+(int)getpid());
```

```
    fprintf(stderr, "\nProcess %d is using CPU: %d. Value of a is %lf and address of a is %p\n", getpid(), cpu, a, &a);
```

```
    sleep(10);
```

```
    fprintf(stderr, "\nProcess %d is using CPU: %d. Value of a is %lf and address of a is %p\n", getpid(), cpu, a, &a);
```

```
    return 0;
```

```
}
```

How to map from virtual to physical?
Let's start from segmentation

Segmentation

- The compiler generates code using virtual memory addresses
- The OS works together with hardware to partition physical memory space into segments for each running application
- The hardware dynamically translates virtual addresses into physical memory addresses

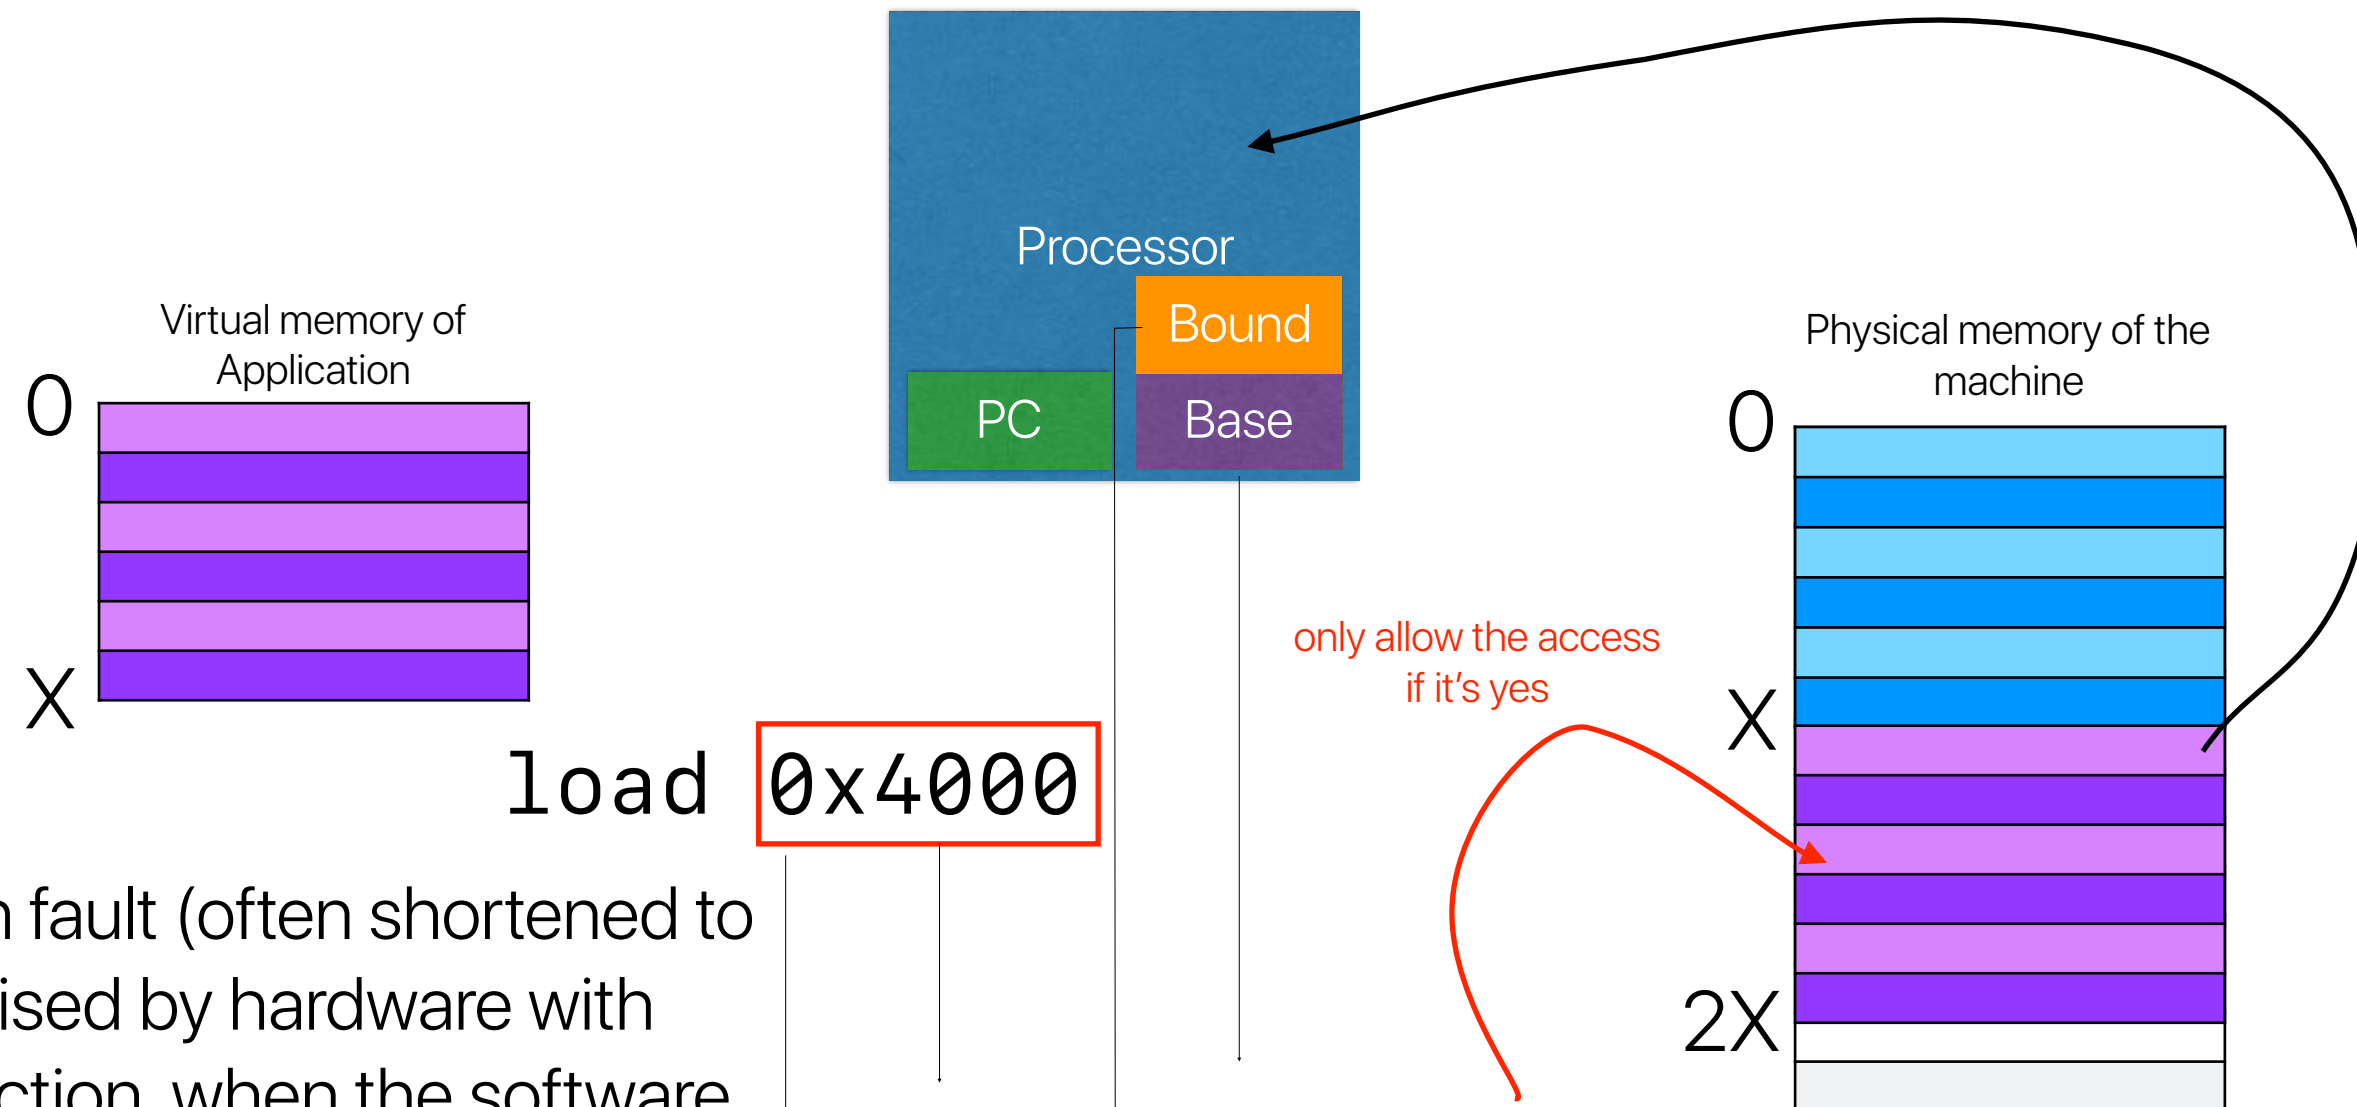

Address translation in segmentation

Protection against malicious processes

Protection against malicious processes

a segmentation fault (often shortened to segfault), raised by hardware with memory protection, when the software has attempted to access a restricted area of memory (a memory access violation).

$$0x4000 + X = X + 0x4000$$

$$0x4000 < X$$

Yes — proceed

No — segmentation fault!!!

What if?

External Fragment

Even though we have space, we still cannot map App. C

Internal Fragment

We waste some space in the allocated segment

**When to create a virtual to physical
address mapping? —
Demand paging**

Demand paging

- **Paging:** partition virtual/physical memory spaces into fix-sized pages
- **Demand paging:** Allocate a physical memory page for a virtual memory page when the virtual page is needed
 - There is also **shadow paging** used by embedded systems, mobile phones — they load the whole program/data into the physical memory when you launch it

Demand paging

- **Paging:** partition virtual/physical memory spaces into fix-sized pages
- **Demand paging:** Allocate a physical memory page for a virtual memory page when the virtual page is needed

Page fault

- Page fault: if the demanding page is not in the physical memory
- How to handle page fault: the processor raises an **exception** and transfers the control (change the PC) to the page fault handler in OS code
 - Allocates a physical memory location for the page
 - Creates an entry recording this allocation — **where?**

Address translation

- Processor receives virtual addresses from the running code, main memory uses physical memory addresses
- Virtual address space is organized into "pages"
- The system references the **page table** to translate addresses
 - Each process has its own page table
 - The page table content is maintained by OS
- In addition to valid bit and physical page #, the page table may also store
 - Reference bit
 - Modified bit
 - Permissions

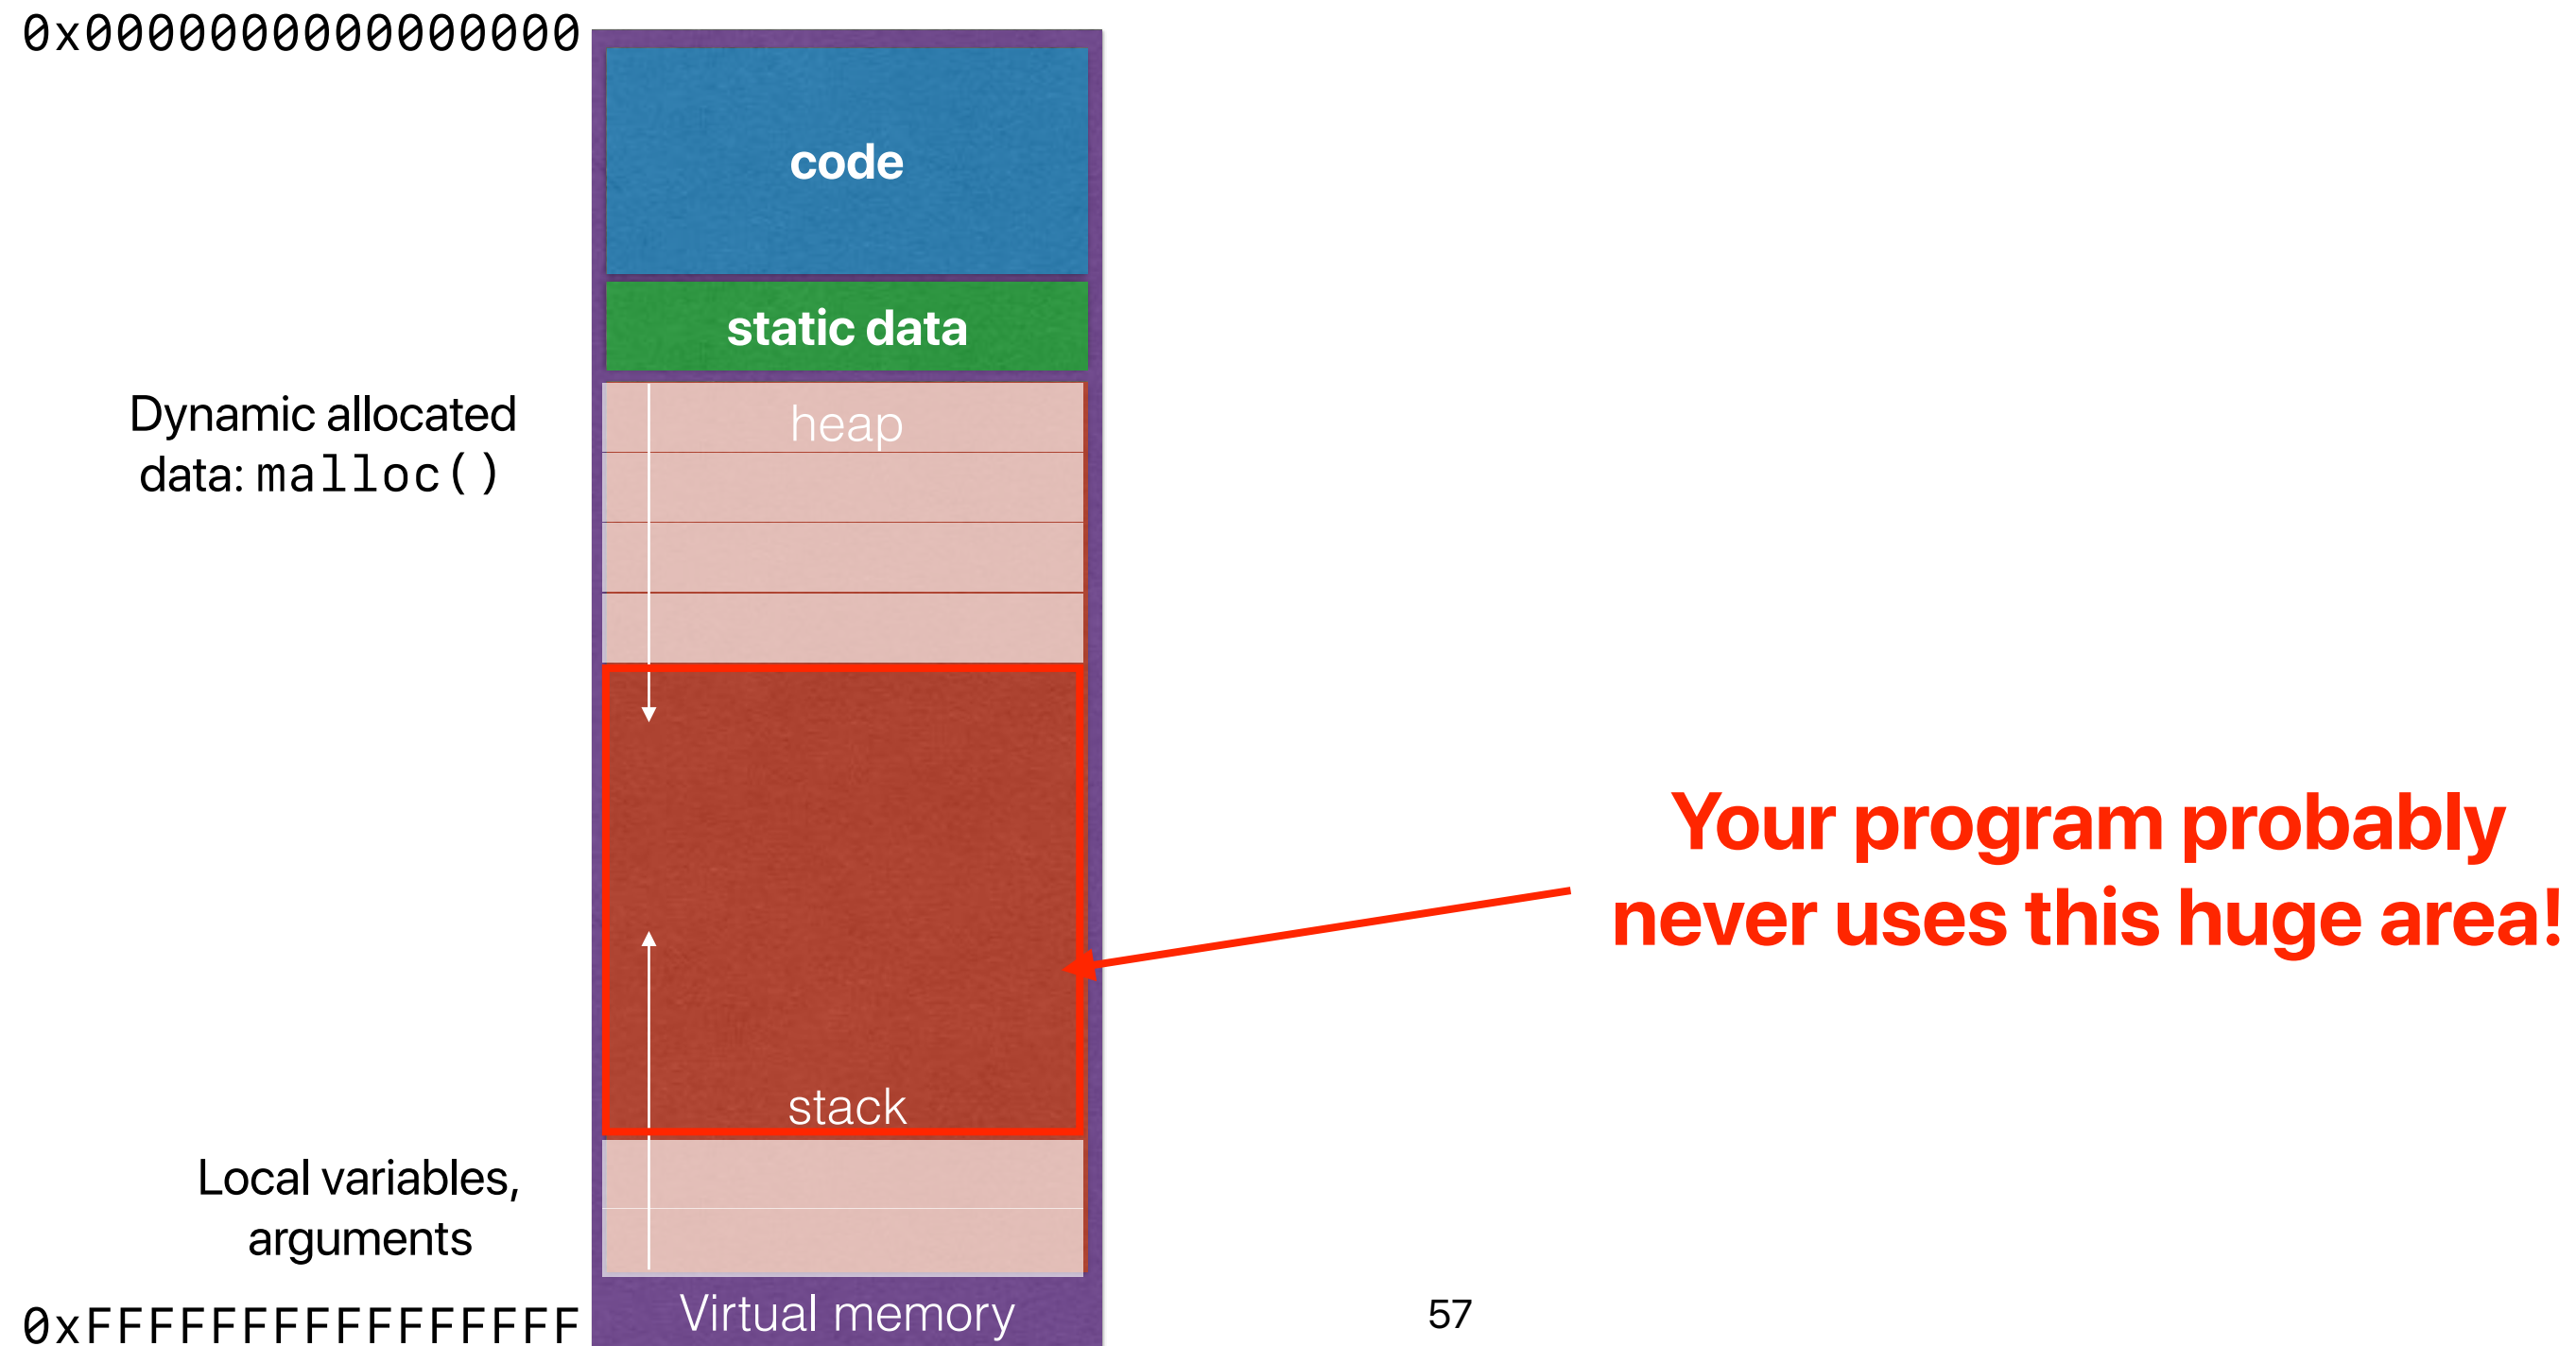

Address translation (cont.)

- Page tables are too large to be kept on the chip (millions of entries)
— space overhead
- Instead, the page tables are kept in memory
— memory access overhead
- Address translation in x86
 - A special register, the page table base register (PTBR), points to the beginning of the page table for the running process
 - The CPU walks through the page table to figure out the mapping
 - The contents of this register must be changed during a context switch

Smaller page tables

Do we really need a large table?

Hierarchical page table

Each of these nodes occupies exactly a page

Otherwise, you always need to find more than one consecutive pages — difficult!

Why?

0x0000000000000000

Hierarchical page table

- Break the virtual page number into several pieces
- If one piece has N bits, build an 2^N -ary tree
- Only store the part of the tree that contain valid pages
- Walk down the tree to translate the virtual address

Page table walking example

- Two-level, 4KB, 10 bits index in each level
- If we are accessing 0x1006000 now...

Hierarchical page table

- Only store the valid second level pages.

Case study: Address translation in x86-64
